Abstract

We study information loss due to gravitational collapse. The mostly uniform primordial density field in the Universe evolved due to gravitational collapse into the large scale structure we see today. In order to gain a better understanding of the early Universe, we study methods of reconstructing this primordial density field by using the information we detect today. We first test the limits of reconstruction by performing a perfect reconstruction in which we use information that is not available to observers. We show that a perfect correlation between the reconstructed field and the initial field cannot be achieved even in the case of this perfect reconstruction. Realistic reconstruction methods based on the Zel'dovich Approximation are then pursued. We use the velocity field to calculate a particle displacement field and reconstruct the density field. We find that the method works very well when starting from redshift $z = 9$, however it breaks down at lower redshifts. To improve the realism of our method, we smooth velocities over 1 Mpc and 10 Mpc scales respectively. We find that a good reconstruction of intermediate scales leads to a loss of information over the large scales.

Chapter 1

Introduction

1.1 Cosmological Context

Cosmology has seen many important advances in the last few decades. Piece by piece we are uncovering the history of the Universe and its components. We now know that our galaxy is just one in trillions (Conselice et al. 2016), and part of a massive web like structure.

Our two main observational tools today, are the cosmic microwave background (CMB) and galaxy surveys. From the CMB we learn about the primordial Universe, and galaxy surveys uncover the nature and structure of the Universe at late times. The latest surveys like Planck (Planck Collaboration et al. 2016) or SDSS (Tegmark et al. 2004) lend strong support to the Λ CDM paradigm. Within this Cosmological Standard Model we now understand most of the important events that shaped the history of our Universe and dictate its future.

The most important components of this model are arguably Dark Matter and Dark Energy. The two account for a total of about 95% of the matter-energy budget of the Universe (e.g. Planck Collaboration et al. 2016). Since their discovery (Babcock 1939, Perlmutter et al. 1999, Riess et al. 1998), we have been able to constrain the properties of the two mysterious components quite well. Most observational probes are consistent with a Cosmological Constant model in which dark energy is considered as a vacuum energy (e.g. Planck Collaboration et al. 2016). However, other models like quintessence, in which dark energy is modelled as an evolving scalar field (Ratra and P. J. E. Peebles 1988), have not yet been excluded. On the other hand, the leading dark matter model is that of a non-interacting (or very weakly interacting) massive particle that only has a gravitational impact (Bertone, Hooper, and Silk 2005).

One of the main goals of modern Cosmology is to study the very early Universe (before the formation of the first stars and galaxies). However, we have

very little direct information from this era (mostly from the CMB). Instead we must turn to indirect sources of information. The structure that we detect in the Universe today evolved through gravitational collapse from that primordial era and therefore hides many of its secrets. The aim of this project is to study methods of recovering this information.

1.2 Observational Probes

1.2.1 The Cosmic Microwave Background

The cosmic microwave background is our main observational tool for studying the early Universe. It is the first light emitted in the Universe after recombination, and it encodes a lot of useful information. The CMB is the most perfect black body ever observed (White 1999). Its existence is already a strong proof in support of the Big Bang model. On the other hand, the anisotropies found in the CMB strongly support both the Λ CDM paradigm and Inflation (e.g. Planck Collaboration et al. 2016).

CMB surveys have measured these anisotropies very accurately (Figure 1.1). They are key in understanding the matter distribution in the Universe. Before recombination, Baryons and Radiation were coupled, so the matter distribution at recombination was imprinted in the CMB distribution. The matter distribution then continued to evolve on its own into the large scale structure we see today. Among the key anisotropies detected in the CMB are Baryon Acoustic Oscillations. This feature is a result of oscillations in the primordial Baryon-Photon plasma (e.g. Bassett and Hlozek 2010). Radiation opposed the collapse of baryonic matter into the potential wells created by collapsing dark matter (which does not interact and is free to collapse). This produced acoustic waves that were imprinted in both the matter distribution (we detect it today in the galaxy distribution) and the radiation distribution (we detect it in the CMB). This probe lends strong support both to the existence of dark matter which plays a key role in their creation, and to that of dark energy (as a cosmological constant) which dictates their evolution at late times (Bassett and Hlozek 2010).

The CMB also has plenty of data in support of Inflation. It shows a uniform, very flat Universe that contains mostly Gaussian anisotropies. All of these are outcomes of inflation and are hard to explain without it. Of particular interest for us are the Gaussian anisotropies. There are many models of inflation, and at the moment we do not have enough precision to distinguish between them. Most models predict some primordial non-gaussianity, however constraining this is key to differentiating between them (Bartolo et al. 2004).

Figure 1.1: Map of the Cosmic Microwave Background acquired by the Planck Space Telescope (Planck Collaboration et al. 2016). After subtracting the effect of our own motion relative to the CMB, the anisotropies only start appearing at $10^{-5}K$. This gives us a glimpse into the primordial matter distribution.

After the CMB was emitted, the Universe entered a period called the Dark Ages. Until the first stars and galaxies formed, the CMB was the only radiation in the Universe. This means we have little to no information about this important era. In it lie the secrets to the formation of the structure we see today in the Universe. This shows the main problem of the CMB, it is primarily a 2 dimensional probe showing us the surface of last scattering. While CMB photons do interact with matter on their way to us producing secondary anisotropies, it is far from a complete picture of the evolution of structure.

1.2.2 Large Scale Structure and Galaxy Surveys

Beginning with the first galaxy surveys in the 1980s (Davis et al. 1982), we started to piece together a picture of the large scale structure of the Universe. Galaxies are clustered together and form massive filaments that are separated by huge voids. This cosmic web is the result of gravitational collapse of initial perturbations. On the other hand, when looking on the largest scales, the Universe is very uniform.

Recent galaxy surveys like 2dF, SDSS and DES (Cole et al. 2005, Tegmark et al. 2004, DES Collaboration et al. 2017) have brought us a wealth knowledge about the Universe today. They are powerful tools for studying the Universe because, unlike the CMB, we now have a 3 dimensional distribution. Future surveys such as LSST (LSST Science Collaboration et al. 2009) and DESI (Levi et al. 2013) are set to map larger and larger areas of the Universe with ever increasing sensitivity.

One of their main objectives is to measure the imprint left by Baryon Acoustic Oscillations in the matter distribution.

This feature is even more important at these late times, because it was locked on a certain scale after recombination. This means we can use it as a characteristic length scale that evolves with Universe. However, there are some problems that also appear. Firstly, galaxies are biased tracers of the underlying matter distribution (e.g. Desjacques, Jeong, and Schmidt 2016). Secondly, non-linear gravitational collapse smears out this feature, reducing the precision of the length scale. As this is a large scale feature, it is however possible to reconstruct it. Eisenstein et al. 2007 argued that most of the contributions to broadening are from super cluster formation and bulk flows. As these large scale features are still in the quasi-linear regime, perturbation theory can be used to perform this reconstruction. Many methods have been proposed to recover this feature. For example, Weinberg 1992 proposed a simple “Gaussianization”, while Nusser and Dekel 1992 and Gramann 1993 introduced a technique based on the success of the Zel’dovich Approximation. More complex methods have also been proposed by Monaco and Efstathiou 1999, Croft and Gaztanaga 1997 and Brenier et al. 2003.

These methods have been instrumental in using survey data to its fullest. Weinberg et al. 2013 estimate that this increase in precision is equivalent to a factor 2 – 4 increase in survey size. In this project we will be attempting to push these reconstruction methods to scales smaller than the BAO. The peculiar velocity field will be of key interest in this endeavour, because most of our work in Chapter 3 is based on it. As the ultimate goal of any reconstruction technique is to be used in practice, we start with an overview of how these peculiar velocities can be measured.

Measuring galaxy velocities has been done extensively through spectroscopic redshift surveys (e.g. Dawson et al. 2013). The problem appears when trying to separate the Hubble flow contribution from peculiar velocities. As peculiar velocities are usually of the order of a few hundred km/sec (Dodelson 2003), they are very hard to detect once we get to scales of 50 to 100 Mpc (with a Hubble flow of $(5 - 10) \times 10^3$ km/sec).

The other widely used technique to measure peculiar velocities is more indirect. We instead construct a 3 dimensional map of the Universe as outlined at beginning of this section. However, to find the distance to an object we are actually measuring its redshift. If we plot this redshift space distribution, we can detect deviations from the expected structure distribution (redshift space distortions). These distortions allow us to indirectly measure peculiar velocities. This technique works very well when studying galaxy clusters (Dodelson 2003).

1.3 The Growth of Structure

In this section, we will take a closer look at some of the tools we use to study the growth of structure in the Universe. The evolution of primordial perturbations into the structure we detect today is studied analytically using perturbation theory (PT). This field can be divided, according to the frame used to study the Universe, into Eulerian PT and Lagrangian PT (LPT). In the Eulerian frame, the evolution of the density of particles is studied (Bernardeau et al. 2002). On the other hand, in the Lagrangian frame, the object of interest is the particle displacement field.

The Eulerian frame has been so widely used to study the growth of perturbations, that we refer to it as Standard Perturbation Theory (e.g. Vishniac 1983, Peebles 1980). The most popular approach is to consider an irrotational fluid characterized by its overdensity and peculiar velocity distributions (Carlson, White, and N. Padmanabhan 2009). However, this method suffers from divergences at large wavenumbers (on small scales). This lead to a number of extensions meant to bring it under control (Crocce and Scoccimarro 2006, Crocce and Scoccimarro 2008).

Lagrangian Perturbation Theory has been well developed in the 1990s (Buchert 1992, Buchert and Ehlers 1993, Buchert 1994). However, it has received less attention partly because the method breaks down after shell-crossing (Carlson, White, and N. Padmanabhan 2009). When two fronts of matter collide, they will mostly pass through each other. If their velocities are not too high they will turn around and start orbiting each other. This event is called shell crossing. Particle motions tend to be very chaotic after shell crossing which means it is very hard to calculate a particle displacement field. Therefore, the Lagrangian picture breaks down. Recently, it has been demonstrated that with some modifications LPT correctly reproduces the SPT power spectrum. Also, even its linear first order approximation correctly predicts the decay of the correlation between the final (non-linear) and the initial fields (Matsubara 2008b, Matsubara 2008a). As this correlation is the main tool used in this project, our main focus will be on the Lagrangian Frame.

Once we get into the deeply non-linear regime, these analytic methods break down. Instead we rely on large N-body simulations to continue our study of the evolution of structure. Generally, these simulations are used to help constrain Cosmological theories of the primordial Universe or to test perturbation theories. A random initial field with properties based on the CMB and our general understanding of the early Universe, is evolved through time until the present. The output of the simulation is then compared to observational data. Simulations like Millennium XXL (Angulo et al. 2012) or Illustris (Vogelsberger et al. 2014) gave

us an unprecedented insight into structure formation and evolution.

On the other hand, simulations are also used as a laboratory for testing reconstruction methods. They give us access to both the initial and the final density fields. We can attempt a reconstruction on the final field and then compare it to the initial field and test how well it worked.

1.4 Recovering Lost Information

As we have seen, the CMB shows us the early Universe as a very uniform field with a mostly Gaussian distribution of anisotropies. This field then evolves into the present day large scale structure of the Universe. The aim of this project is to investigate the information lost during this evolution and methods of recovering it. In Section 1.2.2. we discussed the importance of good reconstruction methods to make full use of galaxy survey data. A very active topic of research is the hunt for non-gaussianities in the primordial Universe. Good reconstruction methods combined with the next generation of galaxy surveys could be instrumental in detecting these non-gaussianities (Bartolo et al. 2004).

In Section 1.2.2 we introduced various reconstruction methods whose main goal is to reconstruct the Baryon Acoustic Peak. This is a large scale feature and therefore attempts at reconstructing it are quite successful. Our objective is to go beyond these scales and attempt reconstructing intermediate scales that are in the non-linear regime.

Information is mostly destroyed on small scales, deep in the non-linear regime. For example, a very large (by scale) primordial underdensity will probably still be an underdensity at late times (as a huge void). On the other hand, a small scale primordial underdensity might be caught in the larger bulk flows and collapse into a larger halo. In this case, the information about the small underdensity is lost.

We will first study the limits of reconstruction techniques in Chapter 2. This will be achieved by performing a ‘perfect’ reconstruction using data that is not available in practice. This also gives us an insight into the information that is actually preserved during gravitational collapse and just needs to be recovered. After that, in Chapter 3, we will move towards realistic reconstructions. In particular, we will use the first order approximation of Lagrangian Perturbation Theory (the Zel’dovich Approximation) to perform our reconstructions. This class of reconstructions uses the velocity field information to reconstruct the density field. Finally, we conclude in Chapter 4 with some of the insights we have gained and interesting results that should be studied further.

Chapter 2

The Perfect Reconstruction

Our first step is to try to understand how much information from the primordial Universe is preserved. We will look at the theoretical limit encountered when trying to reconstruct the final non-linear density field.

As a field is defined at every point in space, any attempt at representing it with data is inherently imperfect. We would have to measure the density field at every point in the Universe in order to obtain all the information it contains. This fact already implies that no data driven reconstruction will ever succeed at perfectly recovering the primordial density field (unless we manage to make an infinity of measurements).

To show this unavoidable loss of information we performed a ‘perfect’ reconstruction. We call this reconstruction ‘perfect’ because it uses data about the initial positions of all particles (which obviously is not available to observers). However, as we will show in this chapter, not even this perfect reconstruction succeeds at perfectly recovering the primordial matter distribution.

2.1 Methods

The first step in studying reconstruction is to find a way to test its effectiveness. To do this, we use cosmological N-body simulations. These simulations give us important insights into how structure evolves in the Universe. More importantly for this project, it allows us to compare any reconstructed density field to the real starting density field. We use data from three simulations available to us. The first one is Simulation A presented in Pontzen, Slosar, et al. 2016 (also referred to as Simulation A in this work). The other two simulations are variations of the same initial setup, with smaller size and smaller resolution respectively. The details of all three simulations are presented in Table 1.

The simulations only contain dark matter and the cosmological parameters

| Label | Size | Number of Particles | Particle Mass (Solar Masses) |
|-------|--------------|---------------------|------------------------------|
| Sim A | $(200Mpc)^3$ | 512^3 | 6.59×10^9 |
| Sim B | $(200Mpc)^3$ | 256^3 | 5.27×10^{10} |
| Sim C | $(100Mpc)^3$ | 256^3 | 6.59×10^9 |

Table 2.1: Details of the three simulations used in this project. They were setup in a way that allows us to study the impact of the resolution (Sim A vs Sim B) and size (sim A vs Sim C)

used were the ones recommended by the WMAP 7-year observations (Komatsu et al. 2011). These are no longer our best estimates (Planck Collaboration et al. 2016), however for our present purposes they are sufficient as we do not compare to observational data. The simulations were evolved from $z = 99$ to $z = 0$ using the P-GADGET-3 code (Springel 2005, Springel et al. 2008).

The idea behind a perfect reconstruction is to use data about the initial state of the simulation to perform the reconstruction. We have access to multiple snapshots at various redshifts in our simulations, including the initial positions of all particles (at $z = 99$). Therefore, we used this information to reconstruct the density field. We first measured the density field of various snapshots in the redshift interval $z = 0 - 9$. The field was measured at the particle positions instead of being measured on a regular grid. This is because the density field will be moved along with the particles as described in the next section. After that, the particle positions were replaced with their initial positions taken from the initial snapshot at $z = 99$.

2.2 From Images to Statistics

2.2.1 The Reconstructed Density Field

As outlined above, the first step is to measure the density field in a snapshot. Each snapshot contains an indexed list with the positions, velocities and masses of all particles in the simulation. In this chapter, only the positions and masses are needed to perform a perfect reconstruction. To perform the first part of this analysis, we used the *pynbody*¹ package (Pontzen, Roškar, et al. 2013).

To have a visual understanding of the reconstruction, we first make some images of the density field. We use *pynbody* to import the initial snapshot and the snapshot at $z = 0$. The density field at the particle locations in the final snapshot is calculated and assigned as the density field of the initial snapshot. Density slices through this reconstructed field are compared to the initial and final fields

¹<https://github.com/pynbody/pynbody>

Figure 2.1: Density slice through Simulation C. The left panel shows the final collapsed density field at redshift 0. The right panel shows the initial smooth density field at redshift 99. The centre panel shows the result of the perfect reconstruction applied to the final field. The collapsed filaments are stretched, but the result is not identical to the initial field. This means there is some information that cannot be recovered.

in Figure 2.1.

We can already see from this comparison that the reconstruction has not recovered all the information, as it is not identical to the initial field. However, the reconstruction spreads out the matter from the collapsed filaments onto a more uniform field. This is exactly the opposite of small initial perturbations collapsing into the filaments. In a way we are trying to run gravity in reverse. Also notice the large difference in the values of the density field. The reconstructed field has density values about 3 orders of magnitude larger than the initial field.

This large difference is an interesting side effect of our method. At late times, most particles tend to be clumped together. Therefore, when measuring the density field at the particle positions, we will mostly get very high values. These values do not change when moving the particles, so the final field will also have very high values, but this time distributed on an almost uniform grid. This results in an apparent increase in the total mass of the simulation. As this increase is just a result of the way we represent the density field, it needs to be accounted for when analysing the results. To conserve the mass of the simulation, we just divide the density field by the ratio of the total final mass to the total initial mass.

2.2.2 Correlation with the Initial Field

In order to get a better understanding of how well this reconstruction worked, we turn to statistics. A good way to represent the reconstruction is to look at the normalized Cross-Spectrum between the initial and the reconstructed field:

$$\frac{P_{IX}(k)}{\sqrt{P_I(k) * P_X(k)}}$$

where I represents the initial field, and X the reconstructed field. The power spectrum is defined as the Fourier transform of the correlation function of the two fields:

$$P(k) = \int d^3y e^{i\mathbf{k} \cdot \mathbf{y}} \xi(y) \quad (2.1)$$

and the correlation function of two overdensity fields is given by:

$$\xi(|\mathbf{x} - \mathbf{y}|) = \langle \delta_A(\mathbf{x}) \delta_B(\mathbf{y}) \rangle \quad (2.2)$$

We used the GENPK code² (Bird 2017) to measure auto and cross power-spectra of GADGET outputs. In order to analyse reconstructed fields, we also modified GENPK to read the fields generated by *pynbody*. However, before calculating the power spectrum, we first calculate the logarithm of the density field.

²<https://github.com/sbird/GenPK.git>

This is an extra step in our reconstruction which has the purpose of reducing the density contrast of the reconstructed field. The initial field has a Gaussian distribution of overdensities. As structure evolves, this distribution becomes skewed towards large scales. It also develops a large positive tail as more and more massive halos are created. However, the negative tail of the function is physically limited by zero density. Therefore, we take the logarithm of this function in an attempt to Gaussianize this distribution and bring it closer to the initial one. We will always perform this step in all our reconstructions.

The original normalized cross-spectra between the initial and the final fields (from Sim A) can be seen in Figure 2.2. For small wavenumbers k (corresponding to large scales), the correlation is very good (converges to 1: perfect correlation). On the other hand, for large wavenumbers (corresponding to small scales), the two fields are completely decorrelated.

The small k convergence towards perfect correlation indicates that information is preserved on these scales. Because of this, both the initial and the final density fields tend to be very uniform, which preserves the correlation. However, over small scales information is lost. The result is a large discrepancy between massive collapsed regions and mostly empty voids. This is in stark contrast to the relative uniformity of the initial field, leading to a breakdown in correlation.

Figure 2.2 also shows the evolution of this correlation with redshift. The wavenumber at which the two fields decorrelate indicates the progress of gravitational collapse at that redshift. This results in the decorrelation scale moving to smaller wavenumbers with the progress of gravitational collapse. The objective of reconstruction methods is to bring this decorrelation scale to larger k (in order to recover information about the initial field).

The errors in Figure 2.2 come from the measurement of the power spectrum. As we have a limited size box, when we measure the largest scales, we only have access to very few modes. This leads to a large error. The errors were propagated without taking into account the correlations between the power spectra when calculating the normalization. However, as these are definitely correlated, this is just an upper bound of the error. The large scale convergence towards perfect correlation also indicates that the actual errors are much smaller. As such, we will not be including them in the following plots.

2.3 Analysis

The results of the perfect reconstruction can be seen in Figure 2.3, where we compare it with the original correlation at different redshifts. The cross-spectra presented show a large improvement in the correlation with the initial

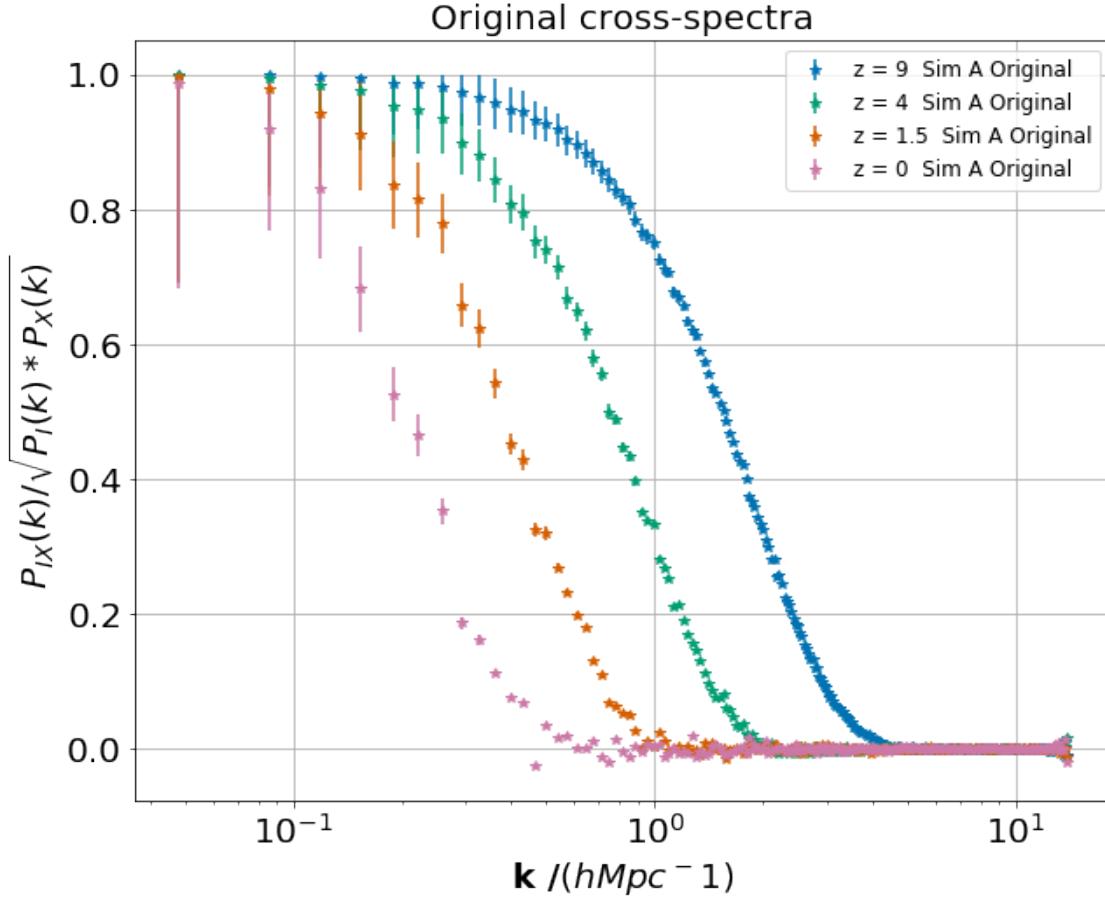

Figure 2.2: Normalized cross-spectra between the initial and final density fields as a function of scale. At small wavenumbers k (large scales) the two fields are perfectly correlated because the Universe is not affected by gravitational collapse over such scales (they are both uniform). On the other hand, at large k (small scales) they are decorrelated because the initial field is very uniform, while the final field is very non-uniform on such scales (it contains large empty voids, and small and massive halos). The decorrelation scale moves to smaller k as time goes on due to the progressive collapse of larger and larger overdensities.

Figure 2.3: Normalized cross-spectra between the initial and the reconstructed fields compared to the original correlation. A large improvement in the correlation was achieved with the perfect reconstruction. This shows up as a shift of the decorrelation scale towards larger k (smaller scales). However, the perfect reconstruction does not lead to a perfect correlation due to the limiting resolution of our density field measurements. When comparing the reconstruction applied to fields at different redshift, we see a trend towards less information at lower redshift. This shows the progress of information loss between $z = 9$ and $z = 0$.

Figure 2.4: Normalized cross-spectra across the three simulations. The left plot shows the original correlation between the initial and the final fields, and the right panel shows the correlation with the reconstructed field. For the original correlations, the size of the simulation plays an important role, with the smaller simulation decorrelating on smaller scales. However, after the reconstruction, the size of the simulation does not seem to have any impact (with Sim A being almost identical to Sim C). In this case, the resolution of the simulation is the only factor that matters, with the larger resolution simulations showing a better correlation.

field. There is also an increase in the amount of information recovered for lower redshifts. This means redshift does not play a role as large in the perfect reconstruction as it originally did.

However, in order to understand this perfect reconstruction, we need to look at the key role played by the resolution of the simulation. Figure 2.4 shows a comparison of the cross-spectra across the three simulations. For the original correlations, the size of the simulation plays a larger role than the resolution. Simulation C (smaller size) shows a smaller scale of decorrelation. Simulations A and B (same size) are very close, with a slight edge for Simulation B (lower resolution).

A completely different structure can be seen once we perform the perfect reconstruction. Simulation A and C (same resolution) show identical reconstructed correlation, while the reconstruction in Simulation B (lower resolution) does not perform as well. This indicates that resolution plays a decisive role in the perfect reconstruction. The other limiting factor is the starting redshift. As we have seen, more and more information is lost as we go to lower redshift. The right panel in Figure 2.4 shows the lowest scale that can be reconstructed from $z = 9$ depending on the resolution of our simulation.

The reconstructions in Figure 2.3 demonstrate that a perfect correlation cannot be achieved even in the ideal case of existing knowledge of all the starting

particle positions. Therefore, we have shown the limits of reconstruction techniques. However, a large improvement in the correlation can be seen, with the decorrelation scale moving to very small scales (of the order $1Mpc$). This ideal reconstruction using perfect knowledge of the particle positions serves as a theoretical upper limit to reconstruction techniques. The perfect reconstruction, along with the original correlation, will always be present in the next chapter when we look at realistic reconstructions. This can give us a better understanding to how well our techniques work.

Chapter 3

Towards Realistic Reconstructions

With the tools developed in the previous chapter, and the perfect reconstruction serving as an upper limit for reconstruction, we are ready to dive into realistic reconstruction methods. In Section 1.2.2 we outlined different reconstruction methods used in practice. This project will study reconstruction within the Zel'dovich approximation. We will use particle velocities to attempt to track their motion back in time. As before, the density field will be carried along with the particles.

3.1 The Zel'dovich Approximation

3.1.1 Background

The central object of Lagrangian Perturbation Theory is the displacement field $\Psi(\mathbf{q})$ which maps the initial particle positions expressed by the Lagrangian coordinate \mathbf{q} to the final comoving Eulerian particle positions \mathbf{x} (Bernardeau et al. 2002):

$$\mathbf{x}(t) = \mathbf{q} + \Psi(\mathbf{q}, t) \quad (3.1)$$

The first order approximation to this equation leads to a separation of variables \mathbf{q} and t (Padmanabhan 1993). After adding the expanding background we obtain the Eulerian particle positions as:

$$\mathbf{r}(t) = a(t)\mathbf{x}(t) = a(t)[\mathbf{q} + b(t)\mathbf{p}(\mathbf{q})] \quad (3.2)$$

Where $\mathbf{r}(t)$ is the Eulerian coordinate, and $a(t)$ is the scale factor.

This approximation was first proposed by Zel'dovich 1970 and it now carries his name, as the Zel'dovich Approximation (ZA). It only works for scales much smaller than the horizon, where Newtonian analysis is possible. However, as our

purpose is to study the growth of structure on scales smaller than the BAO, this approximation is a very good starting point.

An important detail is that the ZA (up to a point) works even in the non-linear regime. This regime is defined in terms of the overdensity δ . When $\delta \sim 1$ we enter the non-linear regime. Standard Perturbation Theory generally breaks down at this point. However, by switching to a description in terms of the particle trajectories, we can reach non-linear density contrasts without the particles being perturbed too much (Padmanabhan 1993).

On a final note, the ZA is very good at predicting the loss of correlation between the initial and the final density fields (e.g. Pontzen, Slosar, et al. 2016). This is the reason we have chosen this framework for our reconstructions.

3.1.2 Tracing particles back

The key ingredient that we will use to perform realistic reconstructions is the peculiar velocity field. The idea behind the Zel'dovich approximation is to calculate a linear displacement field (we refer to this field as the Zel'dovich offset) based on the current peculiar velocities while taking into account the Hubble flow.

The peculiar velocity predicted by the ZA (Padmanabhan 1993) is given by:

$$\mathbf{V}(t) \equiv a(t) \frac{d\mathbf{x}}{dt} \quad (3.3)$$

Using Equation 3.2, we arrive at a peculiar velocity given by:

$$\mathbf{V} = a(t) \dot{b} \mathbf{p}(\mathbf{q}) \quad (3.4)$$

Finally, bringing the displacement field back ($\Psi(\mathbf{q}, t) = b(t) \mathbf{p}(\mathbf{q})$), and switching variables to redshift we obtain:

$$\Psi_z(\mathbf{q}) = \frac{\mathbf{V}(\mathbf{q})}{a(z)} \times \frac{b(z)}{f(z)} \quad (3.5)$$

Where $b(z)$ is called the linear growth factor and $f(z) = \dot{b}(z)$ is the rate of linear growth. To calculate these two, we use the integration methods implemented in *Pynbody* (Pontzen, Roškar, et al. 2013).

As we are interested in looking at the correlation between the reconstructed field and the initial fields in our simulations (which are at $z = 99$), we need to calculate the Zel'dovich offset up to $z = 99$ only. In order to achieve this, we first used equation 3.5 to calculate the offset starting from the redshift z of the snapshot (Ψ_z). After that, we used the same equation to approximate this offset

from $z = 99$ (Ψ_{99}) using the same velocity field. The displacement field we are after is then given by:

$$\Psi(\mathbf{q}) = \Psi_z(\mathbf{q}) - \Psi_{99}(\mathbf{q}) \quad (3.6)$$

3.1.3 The Reconstruction

We first start out in our investigation by performing a reconstruction using the Zel'dovich offset calculated directly from the particle velocities in each snapshot. The methodology of the reconstruction resembles the perfect reconstruction. We first measure the density field at the particle positions in a snapshot, and then we apply the Displacement field $\Psi(\mathbf{q})$ to move the particles. The density field is carried along. After that, GENPK is used to measure the cross power-spectra of the reconstructed field with the initial ($z = 99$) field. This method is still unrealistic as we are using perfect knowledge of all the particle velocities, however it is the first step in our method. Therefore, we want to gain an understanding of how it performs and what are its limitations.

The results of this reconstruction (we call it the Zel'dovich reconstruction) can be seen in Figure 3.1. We again look at the normalized cross-spectra between this reconstruction and the initial density field. To give us a better understanding of how well this method works, the original correlation and the perfect reconstruction are also present. The figure presents the reconstruction starting from four different snapshots in the redshift interval $z = 9$ to $z = 0$.

The reconstruction starting at $z = 9$ gives very good results, bringing the decorrelation scale to an intermediate step between the original and the perfect reconstruction. At this redshift most particles are still in the quasi-linear regime, so this result is not surprising. An interesting feature is the small anti-correlation obtained at large k . This effect is most likely due to particles in non-linear regimes which are past shell-crossing. To understand what gives rise to this anti-correlation, consider two fronts of matter collapsing towards each other. After shell crossing there will be a turn-around as the two evolve into a single filament. If we linearly track these velocities back, we are effectively going the wrong way. This will lead to an anti-correlation over the affected scales. For the $z = 9$ reconstruction, this effect is very small, indicating that shell crossing has only occurred on the smallest scales, and that most particle motions can be well approximated with the linear regime.

However, at lower redshifts most particles are in the non-linear regime. By still treating their motions as linear we are breaking even the correlation that was there to begin with. Figure 3.1 shows the largest scales decorrelating as we move

Figure 3.1: Normalized cross-spectra between the Zel'dovich reconstruction and the initial field. The original and perfect reconstruction correlations are also present to show us where we started and what the limit is. This reconstruction was performed by linearly moving the particles back in time (using the Zel'dovich approximation). As we apply the linear approximation directly to the particle velocities, this gives a good indicator of the regime we are in at that redshift. We see the reconstruction work very well when starting from $z = 9$, which indicates we are still in the quasi-linear regime there. However, as time progresses (lower redshift) the correlation breaks down even on the largest scales, indicating we are mostly in the non-linear regime.

to reconstructions from lower redshifts, and even leading to anti-correlation. For the lowest redshifts, we see a small improvement in the correlation on intermediate scales, but anti-correlation on large scales. This result is much harder to understand. A possible explanation is an extension to the reasons presented above for the anti-correlation in the $z = 9$ reconstruction. The effect of particles that are past shell crossing moving the wrong way increases with decreasing redshift. This might lead to the large scales also becoming anti-correlated. This effect should be studied further, however, we leave this for future works, as our aim in this project is to achieve a good reconstruction.

We found that the Zel'dovich approximation works very well when starting in the quasi-linear regime (e.g. from $z = 9$). On the other hand, it is not a good reconstruction method at low redshift because most particles have non-linear velocities. In this case, higher orders of LPT could perform better. However, at this point it is hard to justify this pursuit from an observational stand point. In this section we have used the peculiar velocities of particles in our simulations. As the ultimate goal of any reconstruction technique is to be used in practice on real data, we need to consider the feasibility of our method. Observers usually detect a few galaxies over an $8 - 10$ Mpc scale (Dodelson 2003), and any peculiar velocity measurements inevitably come with errors. This means that the Zel'dovich reconstruction we just performed is very unrealistic in practice. The goal of the rest of this chapter is to modify the Zel'dovich reconstruction to make it more realistic, and also to improve its performance at low redshift.

3.2 Getting back to linear velocities

In order to make the Zel'dovich approximation work for our reconstruction, we must somehow get back into the quasi-linear regime. As discussed in Chapter 2, matter tends to be collapsed into filaments at late times. This means individual particles have non linear velocities, but ensembles of particles might still move linearly. Our solution to the two problems outlined in the previous section is to use bulk velocities to calculate the Zel'dovich offset, instead of individual particle velocities.

We smooth particle velocities over 1 Mpc and 10 Mpc scales respectively before calculating the Zel'dovich offset. This means we are now considering bulk motions instead of particle motions. These bulk motions will hopefully provide a better start point when we calculate the Zel'dovich offset. This smoothing also improves the realism of our method. Currently, observers can maybe detect a few galaxies in a 10 Mpc bin, so by smoothing our velocity field over that scale, we simulate a more realistic scenario. The reason for attempting a separate re-

construction using velocities smoothed over 1 Mpc scales is twofold. Firstly, we want to understand the effect of the velocity smoothing scale on the reconstruction. Secondly, we use the 1 Mpc case as a test for what could be achieved with improving technology and a better handling of systematics which could be useful for the next generation of Galaxy Surveys.

To perform these reconstructions, we first split a simulation into bins of a given size: $(1\text{Mpc})^3$ or $(10\text{Mpc})^3$. We then use the positions of the particles to identify the bin they are in. After that, an average velocity over the particles in each bin is calculated. This average velocity is assigned to the centre of the bin. In this manner, we construct a three-dimensional grid which contains a measure of the average velocity field. Finally, we use this average velocity field to linearly interpolate the value of the velocities at the particle positions. Particle velocities are therefore smoothed over the scales of interest. Using these new velocities, the Zel'dovich reconstruction is performed as outlined in the previous section.

To further improve the practicality of our method, we also attempt a second type of velocity smoothing. We perform all the steps outlined above to create an average velocity field, but this time we use smaller bins: $(0.5\text{ Mpc})^3$ in size. We then use a Gaussian Filter to smooth this field over the scales of interest (1 Mpc and 10 Mpc respectively). From here, the procedure carries on as outlined above. However, an observer would only detect a few galaxies over a 10 Mpc scale. Also, on these small scales, velocities are most likely still in the non-linear regime. This leads us to perform the Gaussian smoothing over larger scales.

Before we move on to the results, an interesting side effect that should be mentioned showed up during the reconstruction. The nature of our method implies that we are creating coherent movements of particles. This coherent movement leaves large gaps in our reconstructed density field (regions where the density field is equal to 0). These gaps become a problem when we want to take the logarithm of the density field as discussed in Chapter 2. When calculating the density field, *Pynbody* uses a smoothing kernel which normally fills in these gaps. However, this method uses N nearest neighbours to calculate the smoothing scale in a region. Normally, there still are a few particles even in the largest voids. These particles will have very far away neighbours, imposing a large smoothing scale. On the other hand, by creating coherent movements, completely empty regions arise. Particles on the edges of these empty regions can easily find nearby neighbours and establish a relatively small smoothing scale. Our solution is to manually find these empty regions and assign a very small value to the density field.

Figure 3.2: Normalized cross-spectra of realistic reconstructions with the initial field. This figure shows the impact of smoothing velocities over certain scales. Because we lose information by smoothing, the 10 Mpc reconstruction recovers less information compared to the 1 Mpc reconstruction. The Zel’dovich reconstruction is also present for comparison. As we are looking at reconstructions from $z = 9$, they all work quite well because most particles are still in the quasi-linear regime.

3.3 Results

3.3.1 Method analysis

The first step in our investigation is to understand the effect of the velocity smoothing scale on the reconstruction. In section 3.1 we found that the Zel’dovich reconstruction works very well when starting from $z = 9$. We expect our new methods to have a similar performance when starting from this quasi-linear regime.

Figure 3.2 shows the impact of the velocity smoothing on the $z = 9$ Zel’dovich reconstruction. In this case we only present the first method of calculating an average velocity over 1 Mpc and 10 Mpc scales. For brevity, we refer to them as 1 Mpc reconstruction and 10 Mpc reconstruction. As expected, when starting at $z = 9$, both methods work in reconstructing the density field. However, the 1 Mpc reconstruction performs better than the 10 Mpc one. This demonstrates a further loss of information when smoothing the velocity field. The 1 Mpc reconstruction produces a correlation which is very close to the original Zel’dovich reconstruction.

Once we know the impact of the smoothing scale and that the reconstruction still performs very well when starting from $z = 9$, we now want to compare their

Figure 3.3: Normalized cross-spectra of fields reconstructed from $z = 0$ with the initial density field. We compare the two methods of smoothing velocities outlined in Section 3.2 for the two scales of interest. The left panel shows the comparison between the performance of the two methods when velocities are smoothed over 1 Mpc scales, while the right panel shows 10 Mpc scales. If we just average velocities over those scales, we still obtain an anti-correlation over the largest scales. However, when averaging over 0.5 Mpc scales and then applying a Gaussian Filter over the required scales, we see a large improvement in the reconstruction. An interesting effect is that for the 10 Mpc reconstructions, the first method slightly outperforms the second on intermediate scales.

performance when starting from $z = 0$. Figure 3.3 shows the correlation between the $z = 0$ field, reconstructed with the two methods, and the initial field.

A normal velocity average over the interest scales produces results similar to what we found in Section 3.1 with the Zel’dovich reconstruction. We recover some information on intermediate scales, but the large scales become anti-correlated. Here, this seems to be taken to an extreme, in the sense that we have almost perfect anti-correlation on the largest scales. This result is very interesting and should be studied further in the future.

On the other hand, when we use smaller bins and a Gaussian filter, we get a much better correlation. We recover quite a bit of information over intermediate to large scales. However, the largest scales still seem to decorrelate. We will investigate this further in the next section where we compare results from different simulations.

We found that using a Gaussian filter to smooth velocities works much better than normal averaging within the Zel’dovich reconstruction. This indicates that just averaging velocities in a 1 Mpc or even a 10 Mpc bin is not enough to bring us back into the quasi-linear regime. We do see an improvement in the recon-

Figure 3.4: Normalized cross-spectra of reconstructed $z = 9$ fields with the initial field. We compare the same reconstruction methods (1 Mpc smoothing only) applied to two different simulations. On the left is Simulation C with a size of $(100 \text{ Mpc})^3$ and on the right is simulation A with a size of $(200 \text{ Mpc})^3$. The reconstruction in the smaller simulation recovers a lot more information, bringing the correlation very close to the perfect reconstruction.

struction of intermediate scales when going from 1 Mpc to 10 Mpc averaging, but it still leads to an anti-correlation of the large scales.

An interesting outcome of these procedures is also the fact that for a small region, on intermediate scales (for 10 Mpc reconstructions), we do obtain a better correlation using normal averaging. This is probably an indication that we are losing more information when we smooth the field with a Gaussian filter. However, this method works up to much larger scales. By taking into account velocities of particles further away than the scale of interest (even though they have a small weight) we are getting closer to the quasi-linear regime.

3.3.2 Simulation comparison

We now turn our attention to how these methods work when we apply them to different simulations. We have so far only looked at results from Simulation A, as it is the largest one and it has the best resolution. Figure 3.4 presents the correlation of the $z = 9$ reconstructed field with the initial density field in Simulation C and Simulation A. It shows that we are recovering information up to a smaller scale in the smaller simulation (C). This is not entirely surprising, as the smaller simulation is better correlated to begin with (as discussed in Chapter 2). What is surprising is how close to the perfect reconstruction the correlation gets.

The best overall correlation when reconstructing the $z = 0$ density field was achieved in Simulation B. This result is shown in Figure 3.5. Both the 1 Mpc and

Figure 3.5: Normalized cross-spectra of the $z = 0$ reconstructed fields with the initial density field within Simulation B. Our reconstruction methods work very well in this low resolution simulation in the sense that we don’t destroy the correlation that was there to begin with (the largest scales). We also recover some information on intermediate scales, however, it is very far away from the perfect reconstruction. Also, we again encounter the effect found in Section 3.3.1: we recover less information when we smooth velocities over 10 Mpc compared to 1 Mpc.

the 10 Mpc reconstructions achieve a better correlation than the original on most scales. This simulation also gives us the best solution from a practical standpoint. When we calculate the average velocity field using $(0.5 \text{ Mpc})^3$ bins we have, on average, about 0.25 particles per bin. This means that most of our bins are actually empty, which for such small bins is exactly the case for observers as well. This is in contrast with simulation A, which has about 2 particles per bin.

The best results for Simulation A are presented in Figure 3.6. Compared to Simulation B, we recover more information on intermediate scales. However, the largest scales decorrelate. There is also a larger difference between using a 1 Mpc and a 10 Mpc smoothing range. When using a 10 Mpc filter, we recover less intermediate scale information, but the large scales are much better correlated. This is a very good showcase for a trend we have been seeing in this chapter. When we choose to smooth the velocity field we are giving up some information in the hope of recovering the linear regime. The more velocity information we use, the more we destroy the large scale correlation by using the Zel’dovich approximation. However, using more velocity information generally leads to a better

Figure 3.6: Normalized cross-spectra of the $z = 0$ reconstructed field with the initial density field within Simulation A. By smoothing velocities over 10 Mpc scales, we achieve a better correlation of the large scales, however we have a worse correlation over intermediate scales. The result for the intermediate scales was discussed in section 3.3.1. It is an outcome of the information lost when smoothing velocities. The interesting result is that within the Zel’dovich approximation, we manage to preserve the large scale correlation only by using less velocity information.

reconstruction on intermediate scales. This is an interesting information trade-off. The more intermediate scale information we recover, the more large-scale information we lose.

On the other hand, based on these results, a case could be made that by using less velocity information, we are just pushing the problem to larger scales. We still see the largest scales start to decorrelate even when using the Gaussian filter. If we had a much larger simulation with the same resolution we might still see the largest scales become anti-correlated. However, our initial goal was to study reconstruction on scales smaller than the BAO. In that respect, our methods do succeed, as we see an improvement in correlation on intermediate scales.

These results are still quite far away from the correlation we obtain with the perfect reconstruction. However, we only studied reconstructions within the Zel’dovich approximation. Higher orders of Lagrangian Perturbation Theory might be able to get us closer to the perfect reconstruction, and also solve the problem with the information trade-off.

Chapter 4

Conclusions

4.1 Information loss and potential recovery

We studied information loss due to gravitational collapse. Our two main observational probes (CMB and Galaxy surveys) are widely separated by an era from which we have very little information, and which contains such important events as the formation of the first stars and galaxies. It is, therefore, in our interest to find ways of using the data we collect from the Universe today to recover information about the past. Reconstruction techniques have been widely used to recover information on the Baryon Acoustic Peak, but here we look to even smaller scales. Our aim was to test the limits of reconstruction as well as to look at more realistic methods and test their performance.

In Chapter 2, we proved that some information will never be recovered. To show this, a perfect reconstruction was performed. We measured the density field at the particle positions and used the knowledge of the initial particle positions to reconstruct it. Because we do not (and cannot) measure the density field in an infinity of locations, we cannot capture all of its information. This means, no reconstruction is capable of perfectly recovering the primordial density field.

Figure 2.3 shows the normalized cross spectra of our reconstructed fields with the initial density field (versus the original correlation). Our reconstruction recovers plenty of intermediate scale information and the two stay correlated to very small scales. However, on these very small scales, they do decorrelate. This information can never be recovered by reconstructing the density field. The plot shows the most amount of information that could ever be recovered from each redshift. In a way, it shows the limit of what we can ever hope to learn about the primordial density field.

We have also shown that two of the limiting factors in reconstruction are the resolution used and the redshift. Both of these can be improved upon in practice.

More and more information is destroyed with the progress of time. By detecting matter further back in time, we increase the amount of information we can recover. On the resolution side, our limitations are the size of galaxies and how many of them we can detect in a certain volume. Galaxies are also biased tracers of matter, therefore galaxy surveys might not be our best option. A very promising future probe is the Square Kilometre Array (SKA: Dewdney et al. 2009), as it will push both boundaries at the same time. Its goal is to detect atomic hydrogen before reionisation (using the 21cm emission). As we are looking much further back in time ($z > 10$) and directly at the matter distribution, this probe will lead to incredible advancements in our knowledge of the early Universe.

After studying the limits of reconstruction, we turned our attention to more realistic methods in Chapter 3. In particular, we looked at reconstruction methods within the Lagrangian framework. We first start by performing a Zel'dovich reconstruction. Particle velocities are used to calculate a displacement field within the first order approximation of Lagrangian Perturbation Theory (the Zel'dovich Approximation). As before, we calculated the density field at the particle positions and then applied the displacement field to move them back in time. The density field is also carried back in time and reconstructed. We showed that the method works very well when starting at high redshifts ($z = 9$). However, when starting at low redshifts, this method creates an anti-correlation on the largest scales. This is probably caused by the fact that at those redshifts ($z = 0$) most particles have highly non linear velocities, however this phenomenon is not well understood. We left this Zel'dovich reconstruction as just an intermediate step, because of its lack of realism (in practice we could not measure so many velocities so accurately) and its poor performance at low redshifts.

In order to improve the realism and low redshift performance of the method we investigated ways of smoothing the velocity field. We present two methods for achieving this. For the first one, we just average velocities over 1 Mpc and 10 Mpc scales respectively, and interpolate the velocities back at the particle positions. For the second one, we average velocities over smaller scales (0.5 Mpc) and apply a Gaussian filter to smooth this average velocity field over 1 Mpc and 10 Mpc scales respectively. After that, we again interpolate the velocities back at the particle positions. Finally, in both cases we use the smoothed velocities and the Zel'dovich approximation to move the particles (and the density field with them) back in time. These methods are more realistic because we are giving up the accurate and precise knowledge of all the particle velocities. Instead, we now have an average velocity field over certain scales, and this could be measured in practice.

Figure 3.2 shows the impact of smoothing velocities on information recovery.

When we smooth the velocity field, we are giving up some information and this can be seen in a small loss of correlation on intermediate scales. When comparing the two smoothing methods, we found that normal averaging of particle velocities across the scales of interest (1 Mpc and 10 Mpc) does not lead to a large improvement in the $z = 0$ correlation (compared to the the previous Zel'dovich reconstruction). In fact, using this method, the largest scales achieve almost perfect anti-correlation. This is a very interesting result that should be studied further. On the other hand, the second method of using smaller bins to average velocities and then applying a Gaussian filter, works much better. In this case we recover intermediate scale information very well, and the largest scales do not become anti-correlated. Therefore, based on these results, we recommend smoothing the velocity field using small bins (0.5 Mpc) to average velocities and applying a Gaussian filter to smooth velocities over the scales of interest.

The best reconstruction we achieved with this method was using Simulation B (Figure 3.5). In that case, our reconstructions perform better than the original on almost every scale. However, the amount of intermediate scale information recovered is very small. The decorrelation scale does decrease, but very little compared to the perfect reconstruction. On the other hand, when applying the same method to Simulation A (Figure 3.6), we obtain better intermediate scale correlation, but the large scales start to decorrelate. This information trade-off is a trend we have seen throughout Chapter 3. Within the Zel'dovich approximation, whenever we use more velocity information, we recover more intermediate scale information. On the other hand, we lose the large scale correlation that was there to begin with. In the most extreme cases (Figure 4.1), we obtain almost perfect anti-correlation of the largest scales. However, we do succeed in our objective of pushing the boundaries of reconstruction to scales smaller than the BAO.

4.2 Future Work

There were many interesting results discovered during this project. Perhaps the best example is the almost perfect anti-correlation obtained in some cases. Figure 4.1 shows one of the most extreme cases. To perform this reconstruction, we averaged velocities over 1 Mpc bins, interpolated the velocities back onto the particles and then applied the Zel'dovich offset as described in Chapter 3. The resulting correlation is almost a (negative) mirror image of the original correlation. We saw in Section 3.1.3 that the Zel'dovich reconstruction leads to some anti-correlation on the largest scales when starting at low redshifts. This could be explained by the fact that most particles are past shell crossing at this stage. Also, high density collapsed regions tend to have higher peculiar velocities. Because

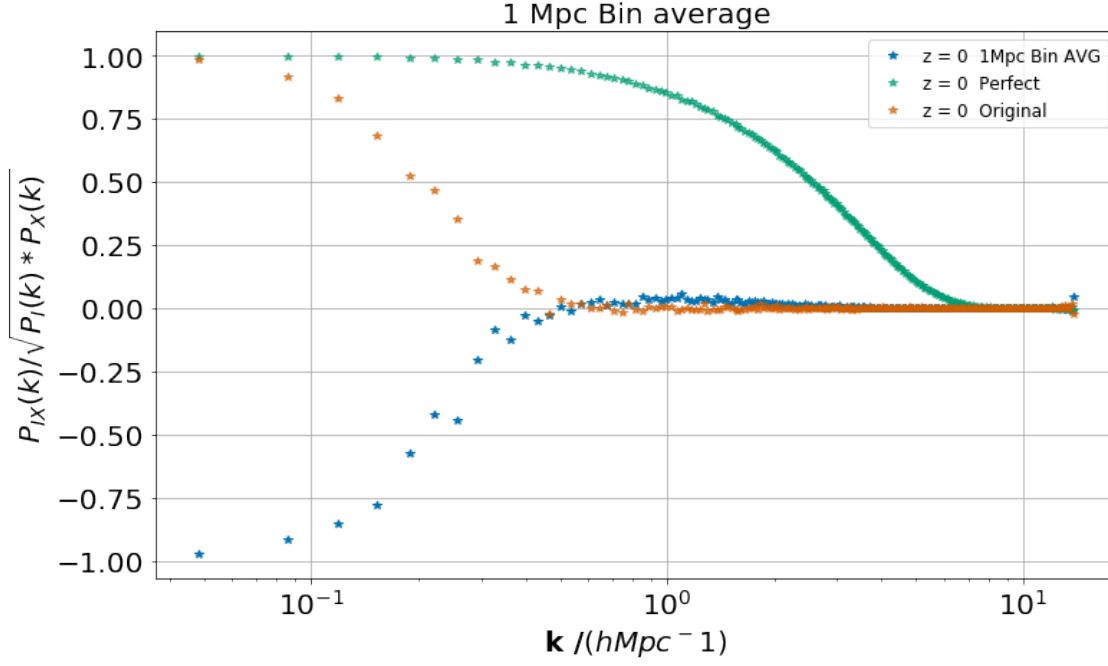

Figure 4.1: Simulation A reconstruction

we just use these velocities just once to calculate the displacement (we don't re-evaluate it as we go back in time), we are displacing most of the matter in these regions. However, we know that this must have been a large overdensity at early times (in order to have formed a massive filament). This then leaves us with an anti-correlation. On the other hand, a perfect anti-correlation of the largest scales is very hard to explain and should be studied further.

Another possible extension of this work would be to smooth the density field. When performing the reconstruction we have assumed perfect knowledge of the final density field, which of course is not the case in practice. Therefore, a further step that would increase the realism of this method would be to also smooth the density field in a manner similar to our smoothing of the velocity field.

The perfect reconstruction has achieved vastly better results than any realistic reconstruction we have attempted. This leads us to conclude that there is much space for the improvement of these methods. We have only used the first order approximation to Lagrangian Perturbation Theory. Higher order approximations could perform better, and also solve some of the problems we encountered.
